## Units

For the purpose of this report, both English and metric (SI) units were employed. The choice of "primary" units employed depended on common reporting standards for a particular property or variable measured. In most cases, the approximate value in the "secondary" units was also provided in parentheses. Thus, for instance, snow density was reported in kilograms per cubic meter $\left(\mathrm{kg} \mathrm{m}^{-3}\right)$ followed by the approximate value in slugs per cubic feet $\left(\mathrm{slug} \mathrm{ft}^{-3}\right)$ in parentheses.

## Vertical Datum:

In this report, "sea level" refers to the National Geodetic Vertical Datum of 1929 (NGVD of 1929), a geodetic datum derived from a general adjustment of the first-order level nets of both the United States and Canada, formerly called Sea Level Datum of 1929.

## Horizontal Datum:

The horizontal datum for all locations in this report is the North American Datum of 1983.

## ACKNOWLEDGMENTS

This project was funded by grant ADN \#2562123, Alaska Department of Transportation and Public Facilities and Department of Natural Resources. Emily Youcha, Joel Homan, Ken Irving, Amy Tidwell, Greta Myerchin, Rena Bryan, and many others participated in snow water equivalent data collection. Peter Prokein assisted with map preparation. Additional snow data is obtained by the National Science Foundation, Office of Polar Programs, Arctic Observing Network project (OPP-0335941, OPP-9814984, and OPP-009615).

## Snow Survey Data for the Central North Slope Watersheds: Spring 2009

## 1. INTRODUCTION

This report is the fourth in a series of snow survey data reports, published each year since 2006 (Kane et al., 2006; Berezovskaya et al., 2007; Berezovskaya et al., 2008). This year's report differs from earlier ones in that it describes in a single document the snow data collected for three projects-Bullen, Foothills, and Umiat Corridor. Discussed in this report are the snow conditions observed during the 2009 end-of-winter snow surveys in watersheds east of the Colville River, including the Anaktuvuk, Itkilik, Kuparuk, Sagavanirktok, Kadleroshilik, Shaviovik, and Kavik River watersheds. Snowpack field studies focused primarily on the maximum snow water equivalent (SWE) accumulation of the 2008-2009 winter and the snowmelt that followed. Field activities started at the end of April because, by then, the snowpack reflects nearly all precipitation that has fallen from October to April (less sublimation) (Benson et al., 1986). Deficiencies in determining snow precipitation and sublimation imply that measurements of snow accumulated on the ground provide the most reliable observational component of the net winter water budget.

Assessment of maximum snow accumulation is critical information in snow hydrology studies. The seasonal snowpack constitutes winter storage of precipitation, induces considerable differences in surface energy balance, and affects the amount of soil desiccation that occurs within the organic layer overlying the permafrost (Kane et al., 1978). Snowmelt is a major hydrological event each year in the Arctic. For many larger river basins on Alaska's Arctic Slope, particularly in the basins of the Colville, and Kuparuk Rivers, peak discharge is the highest during snowmelt. These rivers drain a large area that extends from the Brooks Range through the northern foothills and across the coastal plain before flowing into the Arctic Ocean. Snow starts contributing to runoff in May in the southern foothills, and melting is usually complete within a month. Due to extremely high snowpack heterogeneity, knowledge of SWE spatial distribution is critical for understanding a river basin's hydrologic response during ablation. This report presents snow depth, snow density and snow water equivalent observational
data for the central part of the Alaska's Arctic Slope. It summarizes 2009 data-collection procedures, accuracy of observations, and spatial distribution.

## 2. STUDY AREA

The study domain covers a 200-by-240-km region of Alaska's Arctic Slope (AAS) that is bound by the Brooks Range on the south and the Arctic Ocean on the north, and includes the Anaktuvuk, Itkilik, Kuparuk, Sagavanirktok, Kadleroshilik, Shaviovik, and Kavik River basins. The Anaktuvuk River, which is 215 km long, flows from a glacier in the Endicott Mountains to the Colville River. The Kuparuk River is 240 km long and has a drainage area of about 8140 $\mathrm{km}^{2}$. The Sagavanirktok River is about 290 km long and has a drainage area of about 14,900 $\mathrm{km}^{2}$. More than half (54\%) of the basin area is located in the Brooks Range, and an additional $29 \%$ lies within the Foothills region. Only $17 \%$ of the basin falls within the Coastal Plain region. The Sagavanirktok River is confined between the Kuparuk River basin to the west and the Kadleroshilik and Shaviovik River basin to the east. The Kuparuk, Sagavanirktok, Kadleroshilik, and Shaviovik Rivers flow directly into the Beaufort Sea, while the other streams flow first into Colville River.

Approximately $90 \%$ of the Kadleroshilik River basin consists of coastal plain, with the remaining $10 \%$ in the foothills. The river is approximately 113 km and encompasses over 1500 $\mathrm{km}^{2}$ in drainage area. The Shaviovik River, which is located east of the Kadleroshilik River, is the largest river between the Sagavanirktok and Canning Rivers. The river is 137 km and extends into the Brooks Range. The Shaviovik River drainage basin, approximately $4028 \mathrm{~km}^{2}$ in size, includes the watershed of the Kavik River. The confluence of the Shaviovik and Kavik Rivers is located 18 km from the coast. The Kavik River extends 122 km to the south from this confluence and extends into the Brooks Range.

The southern and northern boundaries of the domain are at $68^{\circ} 10^{\prime} \mathrm{N}$ and $70^{\circ} 15^{\prime} \mathrm{N}$ latitude, respectively. The western and eastern boundaries of the domain are at $150^{\circ} 00^{\prime} \mathrm{W}$ and $146^{\circ} 30^{\prime} \mathrm{W}$ longitude, respectively. Elevation within the study area ranges from sea level to 2675 m ( 0 to 8025 ft ). The topography is characterized by a flat northern portion (generally referred to as

Coastal Plain) and by gently rolling hills and valleys (Foothills) and mountain ridges
(Mountains) of the Brooks Range to the south (Figure 1).

Figure 1. Geographical map of study area. Solid lines show watersheds of major rivers; dashed lines represent approximate boundaries of the Coastal Plain, Foothills, and Mountains regions. Weather stations are shown with star symbol.

Vegetation consists of sedge tussocks and mosses, which cover much of northern Alaska. Occasional groupings of willows, approximately $1 \mathrm{~m}(3 \mathrm{ft}$.) high, occur in hillside water tracts and in valley bottoms. The surface organic soils vary from live organic material at the surface to partially decomposed organic matter between 10 and 20 cm (4 in. -8 in .) in depth. The mineral soil in the glaciated areas is silt overlying glacial till (Kane et al., 1989). Overall, the topography and vegetation of the domain are representative of the AAS region.

## 3. SAMPLING METHODS

Snow surveys are made at designated stations throughout the domain to determine snow depth, as well as vertically integrated density and snow water equivalent. Except when making ablation measurements (see Section 3.2), most of the sites are visited once a year near the peak of snow accumulation, generally the last week of April. Our observations in the Foothills region show that the onset of ablation is typically in May. The end of April is a good time to capture end-ofwinter SWE. March, April, and May are often the months of lowest precipitation, and therefore there is usually little accumulation between the end of winter snow surveys and ablation.

In addition to snow surveys, snow depths are collected continuously throughout the winter at meteorological stations, which are equipped with snow depth sensors. Snow depth sensor readings can be collected in near real time or downloaded in the field directly from a data logger.

### 3.1 Snow Survey

Our snow surveys include gravimetric SWE sampling and snow depth measurements collected over a $25-\mathrm{m}-\mathrm{by}-25-\mathrm{m}$ area; this technique is often referred to as double sampling. The Alaskan snowpack is extremely heterogeneous, with snow depth being more variable than density (Benson and Sturm, 1993). Usually, double sampling yields an areal SWE estimate with a lower variance than is possible using collected snow cores only. Rovansek et al. (1993) showed that double sampling provides improved SWE estimates; they recommended sampling 12 to 15 snow depths for each snow core. This optimal ratio of snow depths to water equivalent, however,
appeared to vary greatly (from 1 to 23), depending on weather and snow conditions. Currently, we use an optimal ratio of 10 ; that is, 50 depths accompany 5 snow cores.

Snow cores are sampled using a fiberglass tube ("Adirondack") with an inside area of $35.7 \mathrm{~cm}^{2}$, equipped with metal teeth on the lower end to cut through dense layers of snow. The advantage of the Adirondack for shallow snowpack is that its diameter is larger than many other types of snow tubes; thus, it provides a larger sample of the shallow Arctic snowpack. To obtain a complete snow core, the Adirondack tube is pushed vertically through the snow while turning, until soil is encountered. At this point, snow depth is recorded. The tube is then driven further into the organic layer and tipped sideways, retaining a vegetation plug; this ensures that the complete snow column was sampled. The vegetation plug is removed and the snow is collected for weighing later in the laboratory. Five snow cores are usually taken to estimate average snow density.

We use constant $50-\mathrm{m}$ lengths for the snow depth course, with a $1-\mathrm{m}$ sampling interval along an L-shaped transect. Twenty-five depth measurements are made on each leg of the L; this strategy is used to account for the presence of snowdrifts in the area of measurement. The directions of measurement are chosen randomly. Snow depth measurements are collected using a T-shaped graduated rod (T-probe). The probe is simply pushed through the snow to the snow-ground interface.

Snow water equivalent is defined as

$$
\begin{equation*}
S W E=\left(S D^{*} \rho_{s}\right) / \rho_{w} \tag{1}
\end{equation*}
$$

where $\rho_{s}$ is average snow density from the 5 snow core samples, $\rho_{w}$ is water density, and $S D$ is an average of 50 snow depths.

### 3.2 Snow Ablation

Starting with the 2007 Kuparuk Foothills snow survey data report, we have summarized longterm snow ablation observations (Table 1) that have been conducted continuously since 1985 from previously funded National Science Foundation, Office of Polar Programs projects.

Table 1. Summary of snow ablation sites from north to south.

| Site Name | Period of Record | Comments |
| :---: | :---: | :--- |
| Betty Pingo | 1993 to 2009 | $\begin{array}{l}\text { Surveyed near NRCS Wyoming gauge. } \\ \text { West Dock }\end{array} 1999$ to 2009 | \(\left.\begin{array}{l}150 m east of West Dock-GC1 Road, approximately one <br>

mile south of West Dock Meteorological Site.\end{array}\right\}\)| Surveyed near Met site 1988 to 1998 (with some missing |

|  |  | to 1997 and at a 6-site transect along UTM 612800 northing |
|  | from 1999 to 2009. |  |

### 3.2.1 Observations from 1985 to 2008

Measurement methods have changed over time as techniques have been modified to improve sampling accuracy and as the study area has expanded. From 1985 to 1992, SWE was estimated from 10 randomly collected snow cores. These cores were sampled using Adirondack tubes and weighed using mechanical scales, calibrated in inches of water. To overcome the difficulty of weighing samples in frequent high-wind conditions, cores were placed in ziplock bags in the field and weighed indoors, using the Adirondack mechanical scale and, after 1999, digital scales.

Following Rovansek et al. (1993), the double sampling technique, which was adopted in 1996, is still used (Section 3.1). During the transition period (1993-1995), 5 to 20 snow cores were taken, along with 50 snow depths. Snow depths have been measured using a variety of devices, such as the Adirondack snow tube, avalanche probes, T-handled graduated probes, MagnaProbe, and ski poles and rods with added graduated scales.

A number of observational sites have changed over time (Table 1). In 1985, SWE and ablation were observed only in the Imnavait Creek basin. Sagwon Hill (SH) and Franklin Bluffs (FR) sites were added in 1986 (although measurements were often lacking). Snow surveys at the Sagwon site were usually made just east of the meteorological site. The Franklin Bluffs sampling site was located from 1986 through 1998, adjacent to the meteorological site 1 km east of the Dalton Highway. In 1999, the snow survey and ablation site was moved west approximately 300 m from the highway. The Betty Pingo site on the Prudhoe Bay Oilfield was established in 1992. This snow survey site is located near the NRCS Wyoming snow gauge about 200 m north of the Kuparuk Pipeline Road between P-Pad and Gathering Center 2. Upper Kuparuk, Happy Valley, and West Dock snow survey and ablation sites were added in 1999.

Imnavait Creek basin (IB) differs from others in that it has the longest period of recorded and detailed observations. Several sites were sampled across the basin to capture basin average SWE. From 1985 through 1997, the Imnavait basin SWE was determined from a transect made across the basin, perpendicular to the stream channel. At this time, snow ablation was tracked only at the west-facing slope adjacent to 4 runoff plots (Hinzman, 1990). In 1989, 2 additional sites were added: 1 in the valley bottom and 1 on the east-facing slope of the basin. To provide consistent identification of sites, the transect has been aligned with 7612800 northing (NAD27, UTM6) since 1999.

### 3.2.2 Observations from 2009

During the 2009 snowmelt season, SWE observations were taken at the Upper Kuparuk station (UKmet), Happy Valley (HV), Sagwon Hill (SH), Franklin Bluffs (FR), Betty Pingo (Betty), and West Dock (WD), and at 6 sites across the Imnavait basin (IB1-IB6). Sites were visited daily or every other day to capture the net volumetric decrease in SWE. We took 5 snow density and 50
snow depth measurements at each site. The snow depth course during snowmelt has an assigned location because of numerous repeated measurements.

### 3.3 Snow-Depth Sensors

The study domain includes seventeen meteorological stations equipped with a sonic snow depth sensor. Five stations were established in the Anaktuvuk River Basin in June 2009. Twelve stations in the Sagavanirktok and Kuparuk River Basin were established in August 2006 (Table 2). The snow depth sensor type is Campbell Scientific Sonic Ranger 50 (SR50) or SR50(A). The only difference between the SR50 and SR50(A) is the housing encasing the ultrasonic sensor. The sensor emits a 50 kHz sound pulse and measures the time the pulse take to return to the sensor. Ultrasonic sensors can measure the distance to any reflective surface like the ground or water, but sensitivity of the SR50(A) is designed for measuring distance to a snow surface.

## Table 2. Meteorological stations with an SR50(A) snow depth sensor included in this report.

|  | Site Name | General Location |
| :--- | :---: | :---: |
| 1 | Accomplishment Creek (DBM1) | Sagavanirktok River, Brooks Range |
| 2 | Ribdon Creek (DBM2) | Sagavanirktok River, Brooks Range |
| 3 | Juniper Creek (DBM3) | Kavik River, Brooks Range |
| 4 | Sag-Ivishak (DBM4) | Sagavanirktok River, Foothills |
| 5 | Upper Kadleroshilik (DBM5) | Kadleroshilik River, Foothills |
| 6 | Kavik (DBM6) | Kavik River, Foothills |
| 7 | Kadleroshilik (DBM7) | Kadleroshilik River, Coastal Plain |
| 8 | Bullen (DBM8) | Near Canning River, Coastal Plain |
| 9 | South White Hills (DFM1) | Kuparuk River, Foothills |
| 10 | White Hills (DFM2) | Kuparuk River, Foothills |
| 11 | North White Hills (DFM3) | Kuparuk River, Foothills |
| 12 | Northwest Kuparuk (DFM4) | Kuparuk River, Foothills |

The method for measuring snow depth with the SR50(A) is simple subtraction. When there is no snow on the ground, the distance measured is the sensor's height above the ground. When snow
has accumulated under the sensor the distance measured is to the snow surface. The difference between distance-to-ground and distance-to-snow surface yields snow depth. For example, if the sensor's height above the ground is 50 inches and 10 inches of snow accumulates, the new distance to surface will be 40 inches. Hence, 40 inches subtracted from 50 inches gives a depthdepth of 10 inches under the sensor.

The ultrasonic pulse has a measurement cone circumference of $22^{\circ}$ from the bottom of the sensor. The program for the $\mathrm{SR} 50(\mathrm{~A})$ records measurements at one minute intervals and reports hourly averages.

## 4. ACCURACY OF OBSERVATIONS

This section reports the problems of measuring and processing observational snow data, so that the reported dataset can be used properly.

### 4.1 Snow Water Equivalent

Snow density and SWE are estimated using snow core sampling. Woo (1997) showed that a larger tube diameter increases the accuracy of density determination; Woo also showed that the Canadian sampler (similar to the Adirondack in diameter) captures snow density within $5 \%$ of snow pit estimates. Our field comparison of Adirondack-to-snow-pit density gives similar results.

The accuracy of a single snow depth measurement depends on properties of underlying organic material. In the area of well-developed organics on top of the mineral soils, snow depth is often overestimated (Berezovskaya and Kane, 2007). While measuring, the probe can easily penetrate low-density organic material, so this additional depth often is incorporated inadvertently into the snow depth measurement. Any type of correction to existing snow depth records is difficult to perform because the error varies strongly from observer to observer and depends on snow and soil conditions at each site.

Whereas snow depths show a systematic overestimation error, snow core densities tend to be close to true value or are underestimated. The difficulty in SWE accuracy interpretations is that actual, accurate SWE is unknown. Comparing different sampling methods, Berezovskaya and Kane (2007) concluded that the SWE of tundra snow, estimated with the double sampling technique, has an error of $\pm 10 \%$.

### 4.2 Snow-Depth Sensors

High frequency, small amplitude noise is inherent in ultrasonic snow depth sensors and can be an impediment to accurate snow accumulation measurements (Brazenec, 2005). Since the speed of sound in air is affected by the temperature of the air it is traveling in, an air temperature is measured to correct distance readings. Sensor mounting height can influence data quality with higher mounting heights resulting in noisier data. Manufacture's stated accuracy is $\pm 1 \mathrm{~cm}$ or $0.4 \%$ of distance to snow surface, whichever is greater (Campbell, 2008). Inaccuracies can be caused by difficulty in establishing a zero point due to tussocks/uneven ground, neglecting periodic maintenance requirements (replacement of sensor transducer), high wind, falling snow, low density snow, blowing snow, and change in sensor height due to ground heave and wildlife curiosities.

Sonic snow depth records in this report were adjusted as necessary to account for field observations and erroneous data points. Typically, erroneous data occurred during high wind/blowing snow events as well as beginning and end of season transition periods. Erroneous data was replaced with values interpolated between the first and last good quality data values. Prior to the 2008-2009 snow season, the ground surface under the snow sensors was trimmed of vegetation and leveled with wood bark. This resulted in improved clarity when deciphering the timing and amount of snow accumulation at the beginning and end of the season.

Diligent field practices are essential for accurate measurements and post-processing data correction and QA/QC purposes. Our field procedures during site visit include:

- Measuring distance from the sensor to the ground during snow free season. This includes five measurements: one distance is measured directly underneath the sensor and four distances are measured at $22^{\circ}$ angles around the sensor.
- Measuring snow depth under the sensor. This includes five measurements: one distance is measured directly underneath the sensor and four distances are measured at $22^{\circ}$ angles around the sensor.
- Measuring distance from sensor to snow surface. This includes five measurements: one distance is measured directly underneath the sensor and four distances are measured at $22^{\circ}$ angles around the sensor.
- Conduct snow survey near the sensor.
- Inspect sensor and supporting structure for structural soundness.
- Inspect sensor for corrosion, ice and hard-packed snow.

## 5. SPATIAL DISTRIBUTION OF SNOW SURVEY SITES

Snow survey sites are chosen to represent snow characteristics over a wide range of vegetation and terrain conditions (Figure 3 and Figure 4). Snow water equivalents are measured at elevations from 4 m to 1474 m ( 13 ft to 4850 ft ) (Appendix A1-A3).

To determine regional average SWE, snow sites are classified as Coastal Plain and uplands; the uplands are separated into Foothills and Mountains. Coastal sites are located below an elevation isoline of $500 \mathrm{ft}(152 \mathrm{~m})$; uplands sites are located above this elevation isoline. The description of uplands snow sites as either Foothills or Mountains is based on elevation and surrounding topography (Appendix A1-A3). Elevation alone is not always representative for classification, because most of the snow survey sites in the mountains are located in valley bottoms where a helicopter can safely access the site.

We also list lake sites that are visited for chemistry data collection (e.g., Chambers et al., 2006). Snow surveys are usually conducted on the lake surface because lake snow is thinner, denser, and harder, and has less SWE than snow on the surrounding tundra (Sturm and Liston, 2003). If time allows, snow surveys are taken on the surrounding tundra also. Lake snow data collection is
not applied to the long-term SWE analysis because different lakes are visited every year. However, lake snow parameters (depth, density, distribution, and thermal properties) are critical input for physical models, to account appropriately for ice thickness and heat loss (Sturm and Liston, 2003). Snow survey measurements were taken on the lake surface of 8 lakes in 2009 (Appendix A3, lines 11-12, 46-51).

Overall, 143 sites were visited in 2009. This number includes 89 sites within the frame of the Foothills project ( 83 snow survey sites and 6 lake sites), 38 sites within the Bullen Point project ( 36 snow survey sites and 2 lake sites), and 16 sites within the Umiat Corridor project. Thirtytwo sites are located in the Mountains and 60 sites are in the Foothills. Snow sites located on the Coastal Plain include 43 snow survey sites and an additional 8 lake chemistry sites with complementary snow survey data (Table 3).

## 6. SNOW SURVEY DATA

The average Coastal Plain snow density ( 0.597 slug $\mathrm{ft}^{-3}, 298 \mathrm{~kg} \mathrm{~m}^{-3}$ ) is higher than the Foothills snow density ( 0.511 slug ft ${ }^{-3}, 263 \mathrm{~kg} \mathrm{~m}^{-3}$ ) and Mountains snow density ( 0.428 slug ft $\mathrm{ft}^{-3}, 221 \mathrm{~kg}$ $\mathrm{m}^{-3}$ ) (Appendix A1-A3)

The average Coastal Plain SWE is 5.1 in . ( 13.0 cm ), and snow depth is 18.6 in . ( 47.2 cm ). The average Foothills SWE is 6.2 in . $(15.6 \mathrm{~cm})$, and average snow depth is 22.9 in . $(58.1 \mathrm{~cm})$. The average Mountains SWE is 3.9 in . $(9.8 \mathrm{~cm}$ ), and average snow depth is 18.0 in . ( 45.8 cm ); both these measurements are generally lower than those of the Coastal Plain and Foothills. Figure 2 and Figure 3 show the snow depth and SWE at each snow survey site. Overall, average end-ofwinter SWE tends to be highest in the Foothills ( $6.2 \mathrm{in} ., 15.6 \mathrm{~cm}$ ) and lowest in the Mountains ( 3.9 in., 9.8 cm ) (Figures 2 and 3, Table 2).

The Mountains and Foothills have more end-of-winter SWE in 2009 compared to the previous years ( $165 \%$ to $233 \%$ of the 2008 SWE). The Coastal Plain has $98-147 \%$ of the last year's end-of-winter SWE (Table 3).

Table 3. Regional snow water equivalent in 2009.

| Region | Number of sites | SWE |  | Percent of last year | Percent of average 2000-2009 |
| :---: | :---: | :---: | :---: | :---: | :---: |

Figure 2. Snow depth (cm) on the North Slope of Alaska in spring 2009. Each point represents average from 50 snow depths.

Figure 3. End-of-winter snow water equivalent (cm) on the North Slope of Alaska in spring 2009.

## Long-term observations in the Kuparuk River

Long-term snow surveys on the AAS have been maintained by the U.S. Department of Agriculture (USDA) since the 1970s. The USDA Natural Resources Conservation Service (NRCS) reports that the SWE on the AAS in 2009 (average from 2 snow courses) accounts for $96 \%$ of the long-term average SWE and the Dalton highway (average from 3 snow courses) has accumulated $95 \%$ of the long-term average SWE (McClure et al., 2009).

Our snow survey dataset collected from the Kuparuk River basin covers a relatively short period of time (2000-2009) when compared with the NRCS period of record, yet it has more detailed spatial coverage: 83 snow courses in the Kuparuk River basin. End-of-winter SWE over the Kuparuk River watershed in 2009 accounts for $128 \%$ of the 10-year average SWE (Table 3). The 2009 end-of-winter SWEs for the Foothills and Coastal Plain represent $135 \%$ and $143 \%$, respectively, of the 10-year average SWE (Table 3). The Foothills and Coastal Plain have the highest 10-year SWE average ( 15.4 and $13.4 \mathrm{~cm}, 6.1$ and 5.3 in .). The Mountains had 8.1 cm (3.2 in.) end-of-winter SWE in 2009, which is more than last year's SWE ( $3.5 \mathrm{~cm}, 1.4 \mathrm{in}$.) but much less than the maximum SWE ( $14.7 \mathrm{~cm}, 5.8 \mathrm{in}$.) measured in 2003. This database has become long enough that we can start to analyze variability from year to year (Table 4).

Table 4. Maximum, minimum, and average snow water equivalent in the Coastal Plain, Foothills, and Mountains regions of the Kuparuk River basin (2000-2009, $n=10$ ), including the basin average.

| Region | Maximum |  | Minimum |  | Average |  |
| :--- | :---: | :---: | :---: | :---: | :---: | :---: |
|  | $\mathrm{cm}($ year) | in. | $\mathrm{cm}($ year) | in. | cm | in. |
| Mountains | $14.7(2003)$ | 5.8 | $3.5(2008)$ | 1.4 | 8.4 | 3.3 |
| Foothills | $15.4(2009)$ | 6.1 | $8.9(2006)$ | 3.5 | 11.4 | 4.5 |
| Coastal Plain | $13.4(2009)$ | 5.3 | $8.4(2001)$ | 3.3 | 9.4 | 3.7 |
| Kuparuk River basin | $12.7(2003)$ | 5.0 | $7.3(2008)$ | 2.9 | 9.6 | 3.8 |

## 7. SONIC SNOW DEPTH DATA

While end-of-winter snow surveys provide areal average snow depth accounting for spatial snowpack heterogeneity, the SR50(A) measures snow depth directly under the sensor during the entire winter. All meteorological stations, except for the South White Hills (DFM1), reported
good quality data during the 2008-2009 winter (Figures 4-15). The South White Hills (DFM1) station had a malfunctioning snow sensor.

The advantage of snow sensor information is its high temporal resolution which can capture the timing and magnitude of snow events. Records show that the snow accumulation began in late September - early October, 2008. The majority of stations reported high snow accumulation (up to $50 \mathrm{~cm} / 20$ inches) in late October - early November, 2008. Following the early season accumulation, the Coastal Plain stations generally remained at a consistent snow depth throughout the season. Snow depth records at Mountains stations have more erosion and accumulation episodes throughout season. Accomplishment Creek, Juniper, Lower Kad, and White Hills stations reported maximum snow depth by January, 2009. Ribdon, Sag-Ivishak, Upper Kad, Kavik, Bullen, Northwest Kuparuk stations reported maximum snow depth in April and May 2009.

Differences in micro-topography and vegetation cause large variability in snow depth at a station, even though the stations are located with the same orographic zone. For instance, White Hills Station (Figure 13) reported shallow snow depths for the entire past three winters. This station is located on top of a ridge, where snow is eroded by persisting strong winds. Kavik Station (Figure 9) reports a relatively shallow snow depth. The immediate surrounding area of this station is flat with low lying vegetation making it susceptible to scouring. Note that the adjacent 50 snow depth measurements show the depths to be generally greater. North White Hills Station (Figure 14) is located on a very slight knoll consisting of tussock tundra compared to the surrounding shrub/high grass environment; the sensor snow depths have consistently over a three year period been less than the adjacent snow surveys.

Snow sensor data used in conjunction with snow survey data can enhance and expand the information gained with each added sampling method. Since a snow depth sensor records snow depth at a point, the additional fifty snow depth measurements near each station represent localscale variability relative to the measurement area under SR50(A) sensor (Figures 4-15 and Table 5). Accomplishment Creek, Kavik, and North White Hills sensor readings reflect the lowest depths measured from snow surveys (Figure 4, 9, and 14 respectively). Ribdon, Juniper, Bullen,

White Hills, and Northwest Kuparuk sensor values are near the middle range of snow survey depths (Figure 5, 6, 11, 13, and 15 respectively). In general, the SR 50 results are lower than the average of the 50 snow depth measurements. There is also considerable variability from year-toyear at a site. At the Ribdon station (Figure 5), at the end of the 2008 winter, the SR50 results compared favorably with the nearby snow survey: however, in 2009 the average was higher. Just the opposite can be found for the Northwest Kuparuk site (Figure 15).

On-site checks as part of the sensor QA/QAC include measurement of four snow depths at a $22^{\circ}$ angle around sensor and one directly underneath. At the time of station visit sensors were reporting typically within $0.5 \mathrm{in}(1.2 \mathrm{~cm})$ of actual snow depth. The greatest discrepancy was Bullen station where sensor values were 4.3 in $(10.9 \mathrm{~cm})$ less than the average observed snow depth (Table 5). Considering all stations the average difference between sensor and measured snow depth is 1.0 in ( 2.7 cm ).

The majority of station data for 2008-2009 winter season reported higher snow accumulation than the previous two years of record (Figures 4-15). Coastal stations, Lower Kadleroshilik (Figure 10) and Bullen (Figure 11), in the northeast of the study area reported similar depths as 2006 and 2007, while coastal plain station, Northwest Kuparuk (Figure 15), located to the west reported greater depths than the previous two years. Generally, Mountain and Foothill stations reported the highest snow depths during 2008-2009 winter, based on observational period from 2006 to 2009.

Table 5. Snow depth information from meteorological station and co-located snow survey. Range and average snow depth from snow survey. Observed snow depth under SR50(A) snow sensor, reported SR50(A) snow depth at time of observed measurement, and difference between observed and reported snow depth.

| Meteorological | Snow Survey | Snow | Observed | SR50(A) | Difference |

Figure 15. Northwest Kuparuk meteorological station hourly SR50 sensor snow depths, observed snow depth under the sensor, and snow survey depths measured near sensor.

Spring 2009 differed in that air temperature rose above freezing for about a week from late April through early May, initiating snow melt (Figure 4 - Figure 15). Our field observations suggest that the snowpack did not reach isothermal conditions at that time, and no runoff was generated. Analysis of sonic snow depth data showed that most of the weather stations reported additional snow accumulation from May 9 to May 15. This rapid accumulation and ablation was more pronounced at stations located to the south and less to the north. No additional snow accumulation was recorded after May 20, 2009.

## 8. ABLATION DATA

Historical ablation data collected at six sites (see Section 3.2) are summarized in Appendix B. The ablation window varies greatly, depending on meteorological conditions and snowpack depth. The 2009 snowpack completely melted by May 26 in northern sites, i.e. Betty Pingo and Franklin Bluffs. It took another week for the snowpack to melt in southern foothills, i.e. the Imnavait Creek basin and Upper Kuparuk (Figure 16). Snowpack across the entire Kuparuk River basin melted by June 12, 2009.

Figure 16. Net volumetric decrease in SWE. Snow ablation curves at the Foothills are shown as dashed lines and, on the Coastal Plain, as solid lines. A shallow snowpack and an early warm event resulted in no measurements being made at the Sagwon site this year

The Imnavait basin ablation curve differs in that it is an average of six sites across the basin. Within a few days of sustained melt, the entire watershed becomes a patchwork of snow-covered and bare tundra. The west-facing slope ( $\sim 80 \%$ of catchment) melts off sooner than the rest of the watershed, because it retains less snow and has more direct solar radiation in the afternoon when air temperatures are highest (Hinzman et al., 1996). In contrast, the east-facing slope has deeper snowpack and receives its maximum irradiance in the morning while convective heat transfer is smaller. Fourteen days were required to complete ablation in the Imnavait watershed in 2009 (Figure 17).

## 9. SUMMARY

This report describes snow depth, snow water equivalent, and snow density data collected in April-May 2009 in the Alaskan Arctic. Snow surveys were conducted in the watersheds of the Kuparuk, Anaktuvuk, Sagavanirktok, Shaviovik, Kadleroshilik, and Kavik Rivers. As of 2009, the Kuparuk River watershed has 10 years of repeated end-of-winter snow survey data. There are snow survey data in the Kuparuk River basin prior 2000, but they were not available for this report. Sagavanirktok, Shaviovik, Kadleroshilik, and Kavik River basins have 4 years of repeated snow surveys data, from 2006 to 2009. Snow survey observations in the Anaktuvuk River basin were initiated in 2009.

Overall, 143 snow survey sites were visited in 2009. This number includes 89 sites within the frame of the Foothills project ( 83 snow survey sites and 6 lake sites), 38 sites within the Bullen Point project ( 36 snow survey sites and 2 lake sites), and 16 sites within the Umiat project.

The Kuparuk River watershed end-of-winter SWE observed in 2009 accounts for $128 \%$ of the 10-year average SWE. The Foothills and Coastal Plain end-of-winter SWE observed in 2009 represent $135 \%$ and $143 \%$, respectively, of the 10 -year average SWE. The Foothills and Coastal Plain have the highest 10-year SWE average ( 15.4 and $13.4 \mathrm{~cm}, 6.1$ and 5.3 in .). The Mountains have 8.1 cm (3.2 in.) of end-of-winter SWE in 2009, which is more than last year's SWE ( 3.5 $\mathrm{cm}, 1.4 \mathrm{in}$.), but less than the maximum SWE ( $14.7 \mathrm{~cm}, 5.8 \mathrm{in}$.) measured in 2003. Snowpack across the entire Kuparuk River basin melted by June 12, 2009.
